

JOURNAL OF MACHINE LEARNING RESEARCH

PUBLICATION AGREEMENT

This is a publication agreement ("this agreement") regarding a written manuscript currently entitled

Deep Generative Analysis for Task-Based Functional MRI Experiments

("the article") to be published in JMLR ("the journal"). The parties to this Agreement are:

Daniela de Albuquerque

(name of corresponding author who signs on behalf of any other authors, collectively "you") and JMLR, ("the publisher").

1. By signing this form, you warrant that you are signing on behalf of all authors of the article, and that you have the authority to act as their agent for the purpose of entering into this agreement.
2. You hereby grant a Creative Commons copyright license in the article to the general public, in particular a Creative Commons Attribution 4.0 International License, which is incorporated herein by reference and is further specified at <http://creativecommons.org/licenses/by/4.0/legalcode> (human readable summary at <http://creativecommons.org/licenses/by/4.0>).
3. You agree to require that a citation to the original publication of the article in the journal as well as a hyperlink to the JMLR web site linking to the original paper be included in any attribution statement satisfying the attribution requirement of the Creative Commons license of paragraph 2.
4. You retain ownership of all rights under copyright in all versions of the article, and all rights not expressly granted in this agreement.
5. To the extent that any edits made by the publisher to make the article suitable for publication in the journal amount to copyrightable works of authorship, the publisher hereby assigns all right, title, and interest in such edits to you. The publisher agrees to verify with you any such edits that are substantive. You agree that the license of paragraph 2 covers such edits.
6. You further warrant that:
 1. The article is original, has not been formally published in any other peer-reviewed journal or in a book or edited collection, and is not under consideration for any such publication.
 2. You are the sole author(s) of the article, and that you have a complete and unencumbered right to make the grants you make.
 3. The article does not libel anyone, invade anyone's copyright or otherwise violate any statutory or common law right of anyone, and that you have made all reasonable efforts to ensure the accuracy of any factual information

contained in the article. You agree to indemnify the publisher against any claim or action alleging facts which, if true, constitute a breach of any of the foregoing warranties or other provisions of this agreement, as well as against any related damages, losses, liabilities, and expenses incurred by the publisher.

7. This is the entire agreement between you and the publisher, and it may be modified only in writing. It will be governed by the laws of the Commonwealth of Massachusetts. It will bind and benefit our respective assigns and successors in interest, including your heirs. It will terminate if the publisher does not publish, in any medium, the article within one year of the date of your signature.

I HAVE READ AND AGREE FULLY WITH THE TERMS OF THIS AGREEMENT.

Abstract

While functional magnetic resonance imaging (fMRI) remains one of the most widespread and important methods in basic and clinical neuroscience, the data it produces—time series of brain volumes—continue to pose daunting analysis challenges. The current standard (“mass univariate”) approach involves constructing a matrix of task regressors, fitting a separate general linear model at each volume pixel (“voxel”), computing test statistics for each model, and correcting for false positives *post hoc* using bootstrap or other resampling methods. Despite its simplicity, this approach has enjoyed great success over the last two decades due to: 1) its ability to produce effect maps highlighting brain regions whose activity significantly correlates with a given variable of interest; and 2) its modeling of experimental effects as separable and thus easily interpretable. However, this approach suffers from several well-known drawbacks, namely: inaccurate assumptions of linearity and noise Gaussianity; a limited ability to capture individual effects and variability; and difficulties in performing proper statistical testing secondary to independently fitting voxels. In this work, we adopt a different approach, modeling entire volumes directly in a manner that increases model flexibility while preserving interpretability. Specifically, we use a generalized additive model (GAM) in which the effects of each regressor remain separable, the product of a spatial map produced by a variational autoencoder and a (potentially nonlinear) gain modeled by a covariate-specific Gaussian Process. The result is a model that yields group-level effect maps comparable or superior to the ones obtained with standard fMRI analysis software while also producing single-subject effect maps capturing individual

differences. This suggests that generative models with a decomposable structure might offer a more flexible alternative for the analysis of task-based fMRI data.

1. Introduction

For twenty years, functional magnetic resonance imaging (fMRI) has been one of the most prominent experimental modalities in the fields of cognitive and clinical neuroscience, allowing researchers and clinicians to investigate relationships between brain regions and functions or behaviors of interest (e.g., memory consolidation (Fogel et al., 2014; Wittmann et al., 2005) and decision making (Hampton and O’Doherty, 2007)). However, the data produced by these experiments — time series of 3D brain images (“brain volumes”) — are both high-dimensional and high-noise and continue to pose daunting analysis challenges (Zhang et al., 2020; Burock and Dale, 2000; Zwart et al., 2008). In particular, each brain volume comprises tens to hundreds of thousands of smaller 3D units (voxels) whose blood oxygen level dependent (BOLD) signal (Ogawa et al., 1992) is captured throughout time.

In response to these challenges, numerous studies have sought to model neuroimaging data, most typically focusing on widely available benchmark datasets using resting state connectivity (Ju et al., 2019; Suk et al., 2016; Mao et al., 2019; Tahmassebi et al., 2018), structural scans (Henschel et al., 2020; Tian et al., 2020; Gunawardena et al., 2017; Zhang, 2018) and fMRI (Gadgil et al., 2020; Riaz et al., 2018; Sarraf and Tofghi, 2016). However, this large and growing literature, which most often focuses on prediction and classification, has largely ignored *task-based* fMRI, data that result from *designed experiments* aimed at testing particular scientific hypotheses. In particular, such data are generated for purposes of *statistical inference* on covariates of interest. Thus, there is a need for models that address both the complexity of fMRI data and the goals of scientific inference.

Here, we take an alternative approach aimed directly at this problem. Since the quantities of interest to experimenters are spatial effect maps that quantify the effects of covariates on brainwide activity, we use a hybrid approach, combining deep generative models (for the maps) with Gaussian Processes (for each covariate) in a generalized additive model (GAM) approach. That is, we “nest” deep generative models inside a well-understood statistical framework that produces separable (and thus interpretable) effect maps for each covariate of interest. As we show, this model produces results comparable to conventional fMRI analysis methods while better capturing spatial variability and allowing for more flexibility in modeling non-linear effects in data.

Generalizable Insights about Machine Learning in the Context of Healthcare

As mentioned, task-based fMRI is a highly popular imaging modality in both basic and clinical neuroscience, as it allows researchers to test hypotheses about brain function in health and disease states through carefully designed and controlled experiments. For example, classic tasks like the *n-back paradigm* (Koshino et al., 2005; Ragland et al., 2002; Blokland et al., 2008) have allowed clinical researchers to discover biomarkers of working memory deficits typically observed in psychiatric diseases like schizophrenia (Jansma et al., 2004; Callicott et al., 2003; Nicodemus et al., 2010) and to relate these to variables of interest such as clinical severity scores (Hashimoto et al., 2009) and genotypes for markers involved in dopaminergic or glutamatergic neurotransmission (Egan et al., 2001; Apud

et al., 2017; Egan et al., 2004). Similarly, fMRI studies have shown that children diagnosed with Autism Spectrum Disorder (ASD) fail to activate sound-processing brain regions in response to vocal sounds (Gervais et al., 2004) and have overall altered activity patterns in key brain regions associated with social functioning (Philip et al., 2012), which might explain the social deficits typically observed in ASD. fMRI has also helped unveil abnormalities in fronto-limbic activation patterns, which has been linked with episodes of mania typically seen in bipolar disorder (Chen et al., 2011). Though these are only a few examples, task-based fMRI is widely used as both a diagnostic and a research method across the brain sciences, where it serves as a key link between higher-level cognitive function, brain spatio-temporal dynamics, and putative molecular and genetic mechanisms of disease.

The alternative fMRI analysis framework we propose here compares favorably to the current state of the art detailed below while harnessing the flexibility of deep generative models to capture high-dimensional and complex data. Moreover, this approach retains the interpretable constructs (effect maps) with which neuroscientists and clinicians are familiar, allowing it to serve as a bridge between established methods and modern techniques. Ultimately, developing better methods to model these data will empower clinicians and neuroscientists to utilize fMRI to its full potential and discover valuable links between molecular mechanisms, neural function and high-level behavior in health and disease.

2. Related Work

Standard approaches to fMRI data analysis routinely make use of compression and dimension reduction-based approaches such as independent component analysis (ICA) (Bai et al., 2007; Calhoun et al., 2009), canonical correlation analysis (Friman et al., 2001; Hardoon et al., 2007; Lin et al., 2014), and less frequently sparse dictionary learning (Lee et al., 2011; Eavani et al., 2012; Wu et al., 2014; Lv et al., 2015), but these approaches typically rely on strong assumptions like linearity and spatial independence which are violated for fMRI data. In addition, SVM-based classification methods, known within the field under the name multi-voxel pattern analysis (MVPA) (Norman et al., 2006; Mahmoudi et al., 2012) have been widely used to localize particular kinds of task effects within the brain while making weaker statistical assumptions.

More recently, there has been an explosion of work using deep networks to model different modalities of brain imaging data, including resting state (rs-fMRI), structural, and diffusion tensor imaging (DTI). For example, deep neural nets have been used to extract latent features from fMRI data, which can then be used for downstream classification tasks (Huang et al., 2016; Jang et al., 2017; Suk et al., 2015; Han et al., 2015). They have also been used for de-noising neuroimaging data (Yang et al., 2020; Zhao et al., 2020). These models have also been extensively used to classify imaging data into different diagnostic groups or into different brain networks (Khosla et al., 2019; Li et al., 2018; Sarraf and Tofghi, 2016; Ju et al., 2019; Ren et al., 2017) and to predict values of regressors of interest from imaging data (Chen et al., 2019; Jiang et al., 2020; Jonsson et al., 2019). These applications have been primarily driven by the advent of public datasets focused on diagnosis and disease prediction, along with the wide availability of modalities like rs-fMRI and DTI, which are comparatively easier to obtain for large cohorts.

However, markedly less attention has been given to the use of deep unsupervised approaches in capturing high-level representations of brain network organization and dynamics directly from low-level brain imaging data. As an example, [Huang et al. \(2017\)](#) utilized a deep convolutional autoencoder to extract high-level representations from task-based fMRI data and found that such representations not only have good correspondence with theoretical models of brain response but are also superior to dictionary learning approaches in detecting task-related regions. [Suk et al. \(2016\)](#) coupled a deep Auto-Encoder with a hidden Markov Model (HMM) to learn non-linear functional relations among brain regions and estimated the dynamics of such relations from rs-fMRI data. More recently, [Qiang et al. \(2020\)](#) adopted neural architecture search along with a deep belief network to achieve an optimal scheme for modeling task-specific and resting state functional brain networks in an unsupervised fashion. Moreover, some of these studies ([Matsubara et al., 2021, 2018](#)) have utilized unsupervised approaches to differentiate between diagnostic criteria and capture the high levels of individual variability typically observed in fMRI data.

The most closely related work to our model is that of [Zabihi et al. \(2021\)](#), which analyzed task-based data using a standard variational autoencoder (VAE). They visualized latent representations across different tasks, showing that these were distinguishable, but they did not examine the role of task covariates or experimental designs. Likewise, [Zhao et al. \(2019\)](#) used a VAE to analyze MRI data with age considered as a covariate, but they did not model task-based data. Thus, to our knowledge, ours is the first work to use autoencoders to address statistical inference in designed experiments, the major goal of scientific analysis in functional MRI experiments. Moreover, the structure of our model differs from the standard VAE in producing covariate-specific, interpretable effect maps for variables of interest, similar to those produced by standard GLM-based approaches.

3. Methods

3.1. Mass univariate regression for fMRI analysis

We denote the brain BOLD signal at time t as \mathbf{x}_t , with individual voxel intensities x_{tj} , where we let j range over all spatial locations. We further assume a set of covariates defined at each time, $\{c_{t\alpha}\}$, where α indexes not only experimental conditions but also nuisance variables like head motion and respiration for which we would like to control. In the mass univariate approach, the effects of these regressors are modeled independently for each voxel:

$$x_{tj} \sim \mathcal{N}\left(\sum_{\alpha} \Gamma_{t\alpha} \beta_{\alpha j}, \sigma_j^2\right) \quad \Gamma_{t\alpha} = c_{t\alpha} * h_t, \quad (1)$$

where $\mathbf{\Gamma}$ is the experimental design matrix. Each column of $\mathbf{\Gamma}$ is formed by up-sampling the original covariate time series, convolving it with the hemodynamic response function h_t (the assumed transfer function between local brain activity and BOLD response), and finally down-sampling the result of this convolution to match the resolution of the sampling rate of the original data ([Woolrich et al., 2001](#)). Typically, the matrix is further processed by de-meaning regressors and performing pre-whitening based on an estimate of the temporal autocorrelation in the data before fitting a General Linear Model (GLM) at each spatial location ([Woolrich et al., 2001](#)). The resulting $\beta_{\alpha j}$ can be viewed as effect *maps* (one per

regressor α) parameterized by spatial location j . In practice, after voxelwise model fitting, summary statistics and estimated covariances are aggregated across separate experimental runs and participants in a manner equivalent to mixed effects models (Beckmann et al., 2003; Woolrich et al., 2004). The downside of this approach, mentioned above, is that there is no sharing of statistical strength across voxels in estimating the maps $\beta_{\alpha j}$. Thus, while cluster corrections and related methods successfully control for false positives, they only indirectly control for false negatives, typically by setting liberal voxelwise statistical thresholds before resampling. In addition these methods ignore the natural correlation structure, both spatial and temporal, present in the data.

3.2. The GAM-VAE model

In contrast, we propose to model entire brain volumes using a single generative model based on variational autoencoders (VAEs) (Kingma and Welling, 2013; Rezende et al., 2014). In the VAE, one assumes a generative model in which the data, \mathbf{x}_t , are drawn from a distribution $p_{\theta}(\mathbf{x}|\mathbf{z})$ that depends on a lower-dimensional latent variable \mathbf{z} and is parametrized by θ . Inference for \mathbf{z} then proceeds by choosing a class of posterior distributions $q_{\phi}(\mathbf{z}|\mathbf{x})$ parametrized by ϕ and minimizing the Kullback-Leibler divergence between the approximate and true posterior, $D_{KL}(q_{\phi}(\mathbf{z}|\mathbf{x})||p_{\theta}(\mathbf{z}|\mathbf{x}))$, over (θ, ϕ) . More concretely, we take

$$p_{\theta}(\mathbf{x}|\mathbf{z}) = \mathcal{N}(\boldsymbol{\mu}_{\theta}(\mathbf{z}), \text{diag}(\boldsymbol{\sigma}^2)) \quad p(\mathbf{z}) = \mathcal{N}(\mathbf{0}, I) \quad q_{\phi}(\mathbf{z}) = \mathcal{N}(\boldsymbol{\nu}_{\phi}(\mathbf{x}), \text{diag}(\boldsymbol{\eta}_{\phi}^2(\mathbf{x}))), \quad (2)$$

where $\boldsymbol{\mu}$, $\boldsymbol{\nu}$, and $\boldsymbol{\eta}$ are functions approximated by deep neural networks, I is the identity matrix, and we allow a separate variance σ_j^2 for each voxel. We then maximize a stochastic approximation to the evidence lower bound (ELBO):

$$\log p(\mathbf{x}) \geq \sum_t \mathbb{E}_{\mathbf{z} \sim q_{\phi}} \log p_{\theta}(\mathbf{x}_t|\mathbf{z}) + \mathbb{E}_{\mathbf{z} \sim q_{\phi}} \log p(\mathbf{z}) + \mathcal{H}[q_{\phi}]. \quad (3)$$

Here \mathcal{H} is the differential entropy of the approximate posterior, and the expectations are approximated by drawing samples (Blei et al., 2017; Kingma and Welling, 2019). We have also assumed that observations \mathbf{x}_t are independent and identically distributed, though this is known to be a poor approximation in the case of highly temporally autocorrelated fMRI data. We justify this on three grounds: First, this mirrors standard fMRI analysis, in which autocorrelation is assumed to be adequately modeled by the autocorrelation of regressors, the convolution by h_t in (1), and a pre-whitening of the design matrix (Woolrich et al., 2001). Second, the sluggishness of the BOLD response in relation to underlying neural activity argues for experimental designs in which temporal dynamics are treated as nuisance variables to be averaged over. Finally, as we shall see, our model naturally lends itself to extensions where the evolution of the latent variables \mathbf{z}_t can be modeled explicitly as in, e.g., (Le et al., 2017; Maddison et al., 2017; Naesseth et al., 2018) or using recurrent neural networks, though we do not pursue that here.

Of course, (2) does not include the effects of the covariates \mathbf{c} . The most general extension is to include these values as inputs to the maps $\boldsymbol{\mu}$, $\boldsymbol{\nu}$, and $\boldsymbol{\eta}$, but in the case of $\boldsymbol{\mu}$, this creates difficulties for interpretability, since the effect of each c_{α} then potentially depends on the values of all other covariates. Instead, we indeed take $\boldsymbol{\nu}(\mathbf{x}, \mathbf{c})$ and $\boldsymbol{\eta}(\mathbf{x}, \mathbf{c})$ but assume for $\boldsymbol{\mu}$

a generalized additive model (GAM) (Hastie and Tibshirani, 1990) in which the observed mean signal is a sum of covariate-specific effects:

$$\boldsymbol{\mu}(\mathbf{z}_t, \mathbf{c}_t) = \beta_0(\mathbf{z}_t) + \sum_{\alpha} (\gamma_{\alpha}(c_{t\alpha}) * h_t) \cdot \beta_{\alpha}(\mathbf{z}_t). \quad (4)$$

$$\gamma_{\alpha}(c_{t\alpha}) \equiv \kappa_{\alpha} c_{t\alpha} + f_{\alpha} \quad \kappa_{\alpha} \sim \mathcal{N}(a, v^2) \quad f_{\alpha} \sim \text{GP}(0, k) \quad (5)$$

That is, we assume a set of effect maps β_{α} parameterized by neural networks and a set of covariate-dependent gain functions γ_{α} . These gain functions are composed of a linear term ($\kappa_{\alpha} c_{t\alpha}$) and a potential non-linearity (f_{α}) drawn from a Gaussian Process with kernel k (Williams and Rasmussen, 2006). As in the general linear approach, each covariate effect γ , representing the neural response, is convolved with the hemodynamic response (h_t), following the steps described in Woolrich et al. (2001), and this result is used to scale the effect map β_{α} . Note that the Gaussian process in (5) does not model γ itself but the *difference* between the covariate effect and its best linear approximation, $\kappa_{\alpha} c_{t\alpha}$. While the GP is theoretically flexible enough to model γ itself, we found that in practice the residual formulation performed better, perhaps because of the difficulty of the GP in capturing a pure linear trend. As a result, the linear coefficients κ_{α} represent the presence or absence of a linear covariate effect, while credible intervals for the GP allow us to assess potential nonlinearity. The result is a model that incorporates the natural covariance structure of brain volumes via the VAE, potentially nonlinear covariate responses via the Gaussian Process, and does so in a manner that preserves experimental interpretability (Figure 1).

More specifically, for the Gaussian Process f_{α} , we use a sparse variational approximation (Hensman et al., 2015) in which the full GP is parameterized by its values at a small set of inducing points $\tilde{\mathbf{c}}_{\alpha}$: $\mathbf{u}_{\alpha} \equiv f_{\alpha}(\tilde{\mathbf{c}}_{\alpha})$. For each covariate, the locations $\tilde{\mathbf{c}}$ and GP values \mathbf{u} of the inducing points are variational parameters to be optimized over, along with the parameters of the kernel $k(\cdot, \cdot)$. With these conventions, we follow (Hensman et al., 2015) in writing (for a single GP)

$$q(\mathbf{f}) = \int p(\mathbf{f}|\mathbf{u})q(\mathbf{u})d\mathbf{u}, \quad (6)$$

where $\mathbf{f} \equiv f(\mathbf{c})$ is the vector of GP values evaluated at the observed covariate values \mathbf{c} and $q(\mathbf{u}) = \mathcal{N}(\mathbf{m}, \mathbf{S})$ is a variational Gaussian posterior over \mathbf{u} . For a model with Gaussian observations, $q(\mathbf{f})$ can be calculated in closed form:

$$q(\mathbf{f}) = \mathcal{N}\left(\mathbf{A}\mathbf{m}, \mathbf{K}_{nn} + \mathbf{A}(\mathbf{S} - \mathbf{K}_u)\mathbf{A}^{\top}\right) = \mathcal{N}(\bar{\mathbf{f}}, \boldsymbol{\Sigma}) \quad (7)$$

with \mathbf{K}_u the matrix formed by evaluating the kernel at each pair of inducing points, \mathbf{K}_{nn} the kernel matrix formed by the data points, \mathbf{K}_{nu} the matrix of kernel distances between inducing points and data points, and $\mathbf{A} \equiv \mathbf{K}_{nu}\mathbf{K}_u^{-1}$. Finally, recalling that $q(\kappa) = \mathcal{N}(a, v^2)$, we can then write (for a single covariate)

$$\gamma = \kappa\mathbf{c} + \mathbf{f} \sim \mathcal{N}(a\mathbf{c} + \bar{\mathbf{f}}, \mathbf{D} + \boldsymbol{\Sigma}), \quad (8)$$

where again, vectors indicate values of the functions at the observed covariate values and $D_{ij} = v^2 c_i^2 \delta_{ij}$ is the (diagonal) covariance of $\kappa\mathbf{c}$. We will use (8) to draw samples for approximating expectations in our training objective.

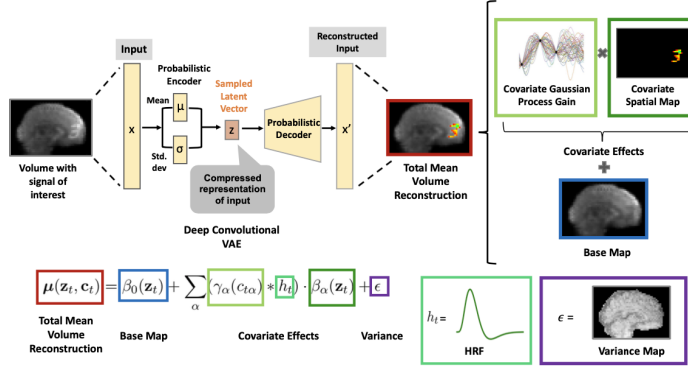

Figure 1: **Schematic of the GAM-VAE fMRI model.** Each fMRI volume is compressed to a lower-dimensional representation using a probabilistic encoder network. Latent space vectors are then sampled and fed to a probabilistic decoder, which yields a base map (blue) and a set of covariate-specific maps (dark green). The gain of each covariate map (light green) is the sum of a linear effect term ($\kappa_{\alpha} c_{t\alpha}$) and a potential non-linearity modeled by a Gaussian process. Finally, the full mean reconstruction of the input is obtained by adding the base and the scaled covariate maps. Variance is modeled on a per-voxel basis, yielding a separate variance map (purple).

3.3. Network Architecture, Training and Map Reconstruction

For the encoder and decoder neural networks, we used a standard convolutional neural network architecture previously used for images (Goffinet et al., 2019), generalized to 3D convolutions for brain volumes. The encoder consisted of 5 convolutional layers, 3 batch normalization layers, and 4 fully-connected layers (see Appendix A for details). Networks responsible for the mean (β_0), covariate-specific (β_{α}) effects, and for the lower triangular and diagonal matrices used to construct the Cholesky factor of the covariance matrix shared both convolutional and fully-connected early layers and so shared feature sets. Analogously, the decoder network consisted of 4 fully-connected layers, followed by 5 transposed 3D-convolutional layers and 3 batch-normalization layers (Appendix A).

For the covariate-specific Gaussian Processes (5), as detailed above, we used the sparse variational approximation of (Hensman et al., 2015) defined at a small number of inducing point locations, and we optimize the parameters of this distribution. More specifically, we fixed a small number of uniformly spaced inducing points per covariate ($\tilde{\mathbf{c}}_{\alpha}$) and learned a posterior over \mathbf{u}_{α} . For our kernels, we used a radial basis function (Gaussian) kernel whose length scale and variance were jointly trained with the VAE.

For our approximate posterior, we take the slope κ and inducing point values \mathbf{u} for each covariate, along with the \mathbf{z}_t , as our latent variables. That is, we take $q(\mathbf{z}, \mathbf{u}, \kappa | \mathbf{x}) =$

$\prod_{\alpha} q(\kappa_{\alpha})q(\mathbf{u}_{\alpha}) \prod_t q(\mathbf{z}_t|\mathbf{x}_t)$ and write the full ELBO as:

$$\begin{aligned}
 \log p(\mathbf{x}) &\geq \sum_t \mathbb{E}_q [\log p(\mathbf{x}_t|\mathbf{z}_t, \boldsymbol{\kappa}, \mathbf{u})] + \mathbb{E}_q [\log p(\mathbf{z}) + \log p(\boldsymbol{\kappa}) + \log p(\mathbf{u})] + \mathcal{H}[q] \\
 &\geq \sum_t \mathbb{E}_q [\mathbb{E}_{p(\gamma_t|\boldsymbol{\kappa}, \mathbf{u})} \log p(\mathbf{x}_t|\mathbf{z}_t, \gamma_t)] + \mathbb{E}_q [\log p(\mathbf{z}) + \log p(\boldsymbol{\kappa}) + \log p(\mathbf{u})] + \mathcal{H}[q] \\
 &= \sum_t [\mathbb{E}_{q(\gamma)} \mathbb{E}_{q(\mathbf{z}_t|\mathbf{x}_t)} \log p(\mathbf{x}_t|\mathbf{z}_t, \gamma) - D_{KL}(q(\mathbf{z}|\mathbf{x}_t)||p(\mathbf{z}))] \\
 &\quad - D_{KL}(q(\boldsymbol{\kappa})||p(\boldsymbol{\kappa})) - D_{KL}(q(\mathbf{u})||p(\mathbf{u}))
 \end{aligned} \tag{9}$$

where the first two lines follow by a double application of Jensen’s inequality, the vector γ once again indicates the estimated gains at the observed data points, and we have used $\mathbb{E}_{q(\gamma)} = \mathbb{E}_{q(\boldsymbol{\kappa}, \mathbf{u})} \mathbb{E}_{p(\gamma|\boldsymbol{\kappa}, \mathbf{u})}$ in the third line. As is typically done, we approximate the sum over data points by a randomly selected minibatch of size $B \ll N$ and approximate the expectations via samples: $\mathbf{z}_{t*} \sim q(\mathbf{z}_t|\mathbf{x}_t)$ and $\gamma_* \sim q(\gamma)$, where γ is now evaluated only at points in the *minibatch* and sampling is done via (8). This yields the doubly stochastic ELBO

$$\begin{aligned}
 \log p(\mathbf{x}) &\gtrsim \frac{N}{B} \sum_{t \in \mathcal{B}} [\log p(\mathbf{x}_t|\mathbf{z}_{t*}, \gamma_*) - D_{KL}(q(\mathbf{z}|\mathbf{x}_t)||p(\mathbf{z}))] \\
 &\quad - D_{KL}(q(\boldsymbol{\kappa})||p(\boldsymbol{\kappa})) - D_{KL}(q(\mathbf{u})||p(\mathbf{u})).
 \end{aligned} \tag{10}$$

The divergence terms in (10) can be recognized as regularizers that encourage the approximate posteriors to remain close to their respective priors (Hoffman and Johnson, 2016), and it is well-established that there are benefits to both disentangling in the latent space and robustness in upweighting such terms (Higgins et al., 2017; Hoffman and Johnson, 2016). Details of computing these KL divergences in closed form can be found in Appendix B. In what follows, we replace the weighting by $\frac{N}{B}$ by an additional hyperparameter ρ to arrive at our composite objective:

$$L(\gamma_{\alpha}, c_{t\alpha}, z_t) = -\text{ELBO} + \rho \sum_{\alpha} \text{GPD}_{\text{KL}}(\gamma_{\alpha}(c_{t\alpha})) + \delta \sum_{\alpha} \|\beta_{\alpha} - \hat{\beta}_{\alpha}\|^2, \tag{11}$$

In this objective, the first term represents the classic ELBO objective for the VAE, the second term (GPD_{KL}) represents the sum of the KL divergence terms for $q(\boldsymbol{\kappa})$ and $q(\mathbf{u})$, and the third term is an additional regularizer, which biases the model toward effect maps close to the estimated GLM solution: $\hat{\beta} = (\Gamma^{\top} \Gamma)^{-1} \Gamma^{\top} x$. Using these solutions, which can be efficiently computed even for large data sets, substantially improved the final learned maps. In practice, we used the design matrix produced by FSL’s FEAT module in computing $\hat{\beta}$, which includes the up-sampling, HRF convolution, downsampling, and pre-whitening described in Woolrich et al. (2001).

The full GAM-VAE model was trained via using the Adam optimizer, approximating gradients using samples from the approximate posteriors to compute expectations in (9) (Blei et al., 2017; Kingma and Welling, 2019). Hyperparameters ρ and δ were chosen via grid-search in a held out sample ($n=3$ subjects), using different possible values sets $((1, 10, 50, 100)$ for ρ and $(0.05, 0.5, 1.0 \text{ and } 2.5)$ for δ , respectively) to yield mean reconstructions

with the highest visual quality (see Appendix C). For our synthetic signal experiments (see below), we used $(\rho, \delta) = (10, 0)$ and for the experiments validating on biological effects we used $(\rho, \delta) = (10, 1.0)$.

4. Cohort and Data

Data consisted of 8 subjects (6 female, age = 31.13 ± 7.7 yrs), whose fMRI data were acquired as a part of the neurofeedback task of the NKI-Rockland sample (Nooner et al., 2012). Briefly, the NKI-Rockland sample consists of data from a total of 180 residents of Rockland, Westchester, or Orange Counties (NY) or Bergen County (NJ), aged 21–45 years. This sample uses *minimal* psychiatric exclusion criteria — i.e., it excludes subjects with Global Assessment of Function (GAF; DSM-IV) below 50, history of acute or chronic substance abuse, of psychiatric hospitalization, diagnosis of schizophrenia, or prior suicide attempts requiring medical intervention. It also excludes individuals with other chronic or serious medical conditions (e.g., epilepsy, TBI, stroke). For a full description of medical exclusion criteria, see McDonald et al. (2017).

Data were acquired using a 3T Siemens Magnetom TrioTrim scanner (TR = 1400 ms, TE = 30 ms, voxel size = $(2.0\text{mm})^3$, flip angle = 65 degrees, FoV = 224 mm) (Nooner et al., 2012). The Checkerboard Task, in which subjects were presented either a checkerboard or a fixation cross on a gray background screen, utilized a block design, with each block lasting 20s and a total of four blocks per category (i.e., four checker, four fixation-cross). This task is known to evoke strong activity in brain areas responsible for visual processing (Nooner et al., 2012).

4.1. Data Preprocessing

For each subject, data preprocessing consisted of motion-correction, registration to each subject’s structural scan (T1w), warping to MNI space, brain-masking and down-sampling to $41 \times 49 \times 35$. No spatial smoothing was applied, and slice-timing correction was omitted, since data are multi-band. Finally, single volumes were normalized globally (i.e., across all subjects) prior to being fed to the GAM-VAE model. Task covariates included the task period itself (representing the effect of checkerboard presentation) plus 6 motion regressors (3 translational, 3 rotational). For analysis, only brain activity-related covariates (in this case task period) were convolved with the hemodynamic response function (HRF) in (4). Here, following the structure of FSL’s FEAT module, we modeled the HRF using a double gamma structure, with two separate gamma probability density functions to capture the peak ($g_1(t) = \text{Ga}(t; k = 6, \theta = 1)$) and the post-stimulus undershoot ($g_2(t) = \text{Ga}(t; k = 12, \theta = 1)$). These two gamma distributions were combined to yield the hemodynamic response function (Figure 1):

$$\text{HRF}(t) = g_1(t) + 0.35g_2(t) \quad (12)$$

4.2. Evaluation Approach/Study Design

The goal of our experiments is to compare the GAM-VAE approach to the current standard of practice analysis approach, the mass univariate model. For these analyses, we used FSL

(Jenkinson et al., 2012; Woolrich et al., 2009; Smith et al., 2004). We also compared selected analyses with another widely used software package, SPM (Penny et al., 2006), which produced very similar results. Since standard methods have been the subject of nearly two decades of active development, our tests were aimed at providing evidence that (a) our model, which uses approximate Bayesian methods, nonetheless controls for false positive rates when a ground truth effect is known to be present; (b) these properties degrade gracefully as the signal to noise ratio of the effect is lowered; and (c) the GAM-VAE could produce equivalent (or better) effect maps to those found via standard approaches. That is, we investigate both the power and calibration of our model, as well as its interpretability.

4.3. Results on Synthetic Experiments

A key difficulty in assessing the performance of statistical methods on fMRI data is that true synthetic data are challenging to simulate, while ground truth effects are unknown in real data. Thus, to test how well the proposed model can recover a known ground truth signal, we added a synthetic regressor, a large (13×13) hand-written “3,” to the checker dataset volumes, creating new, altered datasets. More specifically, the added signal was placed at a constant location in the frontal lobe, with varying signal intensities (2000, 1500, 1000, and 400 arbitrary units (a.u.)). The intensity of the added signal was constant across all voxels and varied only across tests and was active only during control/fixation blocks so as to overlap minimally with time points at which the visual checkerboard stimulus was presented.

We trained the GAM-VAE model on these altered datasets for 400 epochs, at which point convergence was achieved and reconstructions had good visual quality on inspection. For these control simulations, we randomly initialized all contrast maps and no GLM regularization was applied (i.e., $\delta = 0$). Additionally, since the added signal is artificially introduced (and, therefore, not subject to hemodynamic filtering), we did not convolve the GP for the synthetic regressor with the HRF.

Figure 2 shows the resulting average maps (across-participants) for the synthetic regressor effect. Panel A shows a map of the ground-truth signal, overlaid on an anatomical standard template. Panel B shows the average maps generated by our model capturing the synthetic signal across four different signal intensities (e.g., 400, 1000, 1500 and 2000 a.u.). For each intensity, the model was trained using 3 different seeds (rows in panel B). As expected, the model can correctly recover the shape of the synthetic effect for higher signal intensity values, with reconstruction degrading as signal strength decreases.

Figure 3 shows a quantitative assessment of our model’s ability to estimate the effect size of this synthetic regressor. To perform this analysis, we mimicked a real experiment (in which the shape of the signal would be unknown) by analyzing data within a spherical mask centered on the location of the synthetic signal. We then defined total effect size as the sum of the intensities of all voxels within the mask. Likewise, we performed standard mass univariate GLM analysis on these data and used the same masking approach (mask was applied to the un-thresholded and un-corrected average contrast maps), and compared both results to the ones obtained for the ground truth maps. As Figure 3 shows, both our proposed GAM-VAE model and the GLM underestimate effect sizes in general, though our model comes closer to correctly estimating effect sizes.

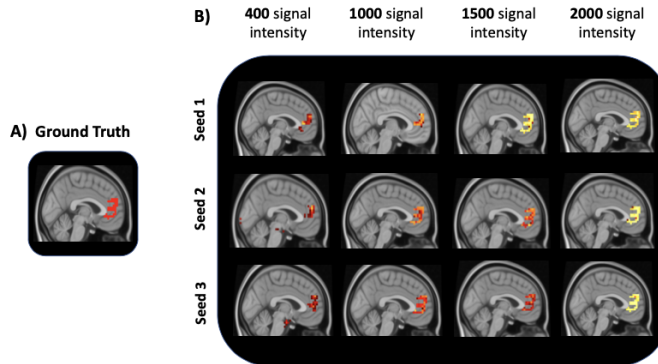

Figure 2: **Performance of the GAM-VAE model on synthetic data.** A: Ground truth effect map for synthetic regressor added. B: Average synthetic regressor maps at different signal intensity values (3 different seeds per intensity).

Figure 3: **Effect Sizes predicted by GAM-VAE model and GLM vs. ground truth for different signal intensities.** Effect sizes were computed as the sum of surviving voxels inside a spherical mask centered on location of the original ground-truth signal. Green, blue and purple lines represent ground-truth, GAM-VAE and GLM effect size estimates, respectively. Error bars represent standard deviation across three independent simulations carried out for each signal strength. Both models underestimate the ground truth effect size, though the GAM-VAE is slightly more accurate, coming closer to the true effect sizes.

5. Results on Visual Stimulation Data

To assess the ability of the GAM-VAE to infer well-validated biological effects, we trained the model using a benchmark dataset consisting of repeated presentations of a visual stimulus. For these data, the model was trained for 400 epochs, at which point convergence was achieved and reconstructions had good quality upon inspection. To aid convergence,

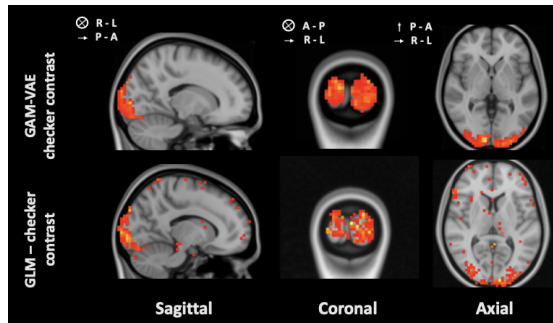

Figure 4: **Average effect maps for visual data set experiments.** Group average maps generated by the proposed GAM-VAE model (top row) vs. the GLM (bottom row). Note that GAM-VAE model not only captures V1 effect appropriately, but also produces smoother and more contiguous clusters, with fewer spurious activations outside of V1.

we applied a regularization term which enforced our model to produce solutions close to the GLM estimates (11, $\delta = 1.0$).

Figure 4 shows the resulting group average task contrast map generated by our model, along with the average contrast map obtained using the standard GLM approach. Note that the GAM-VAE effect map appears smoother and exhibits both fewer spurious activations outside of visual cortex and fewer “missing” voxels than the GLM map (see credible intervals for $q(\kappa)$ and sample $\gamma(c_{t\alpha})$ plots in Appendix D). In Figure 5 we also show comparable task contrast (visual stimulus on versus off) maps for two sample participants. These maps are generated by averaging across all task-containing volume reconstructions for each given subject. As can be seen, the exact location and spatial extent of the stimulus effect varies slightly from subject to subject, though all subjects show a consistent response around visual area V1 (see maps for the remaining 6 subjects in Appendix E). Thus, our model is able to capture both population-level inferences and individualized effect estimates.

It is also of interest to note that analysis run-time across all levels took approximately 13 hours total for this small cohort ($n = 8$). While this is comparable to run times using the standard approach, our model has the potential to yield significantly lower run times for larger data sets (e.g., data sets with more runs and more subjects). This is because our model does not require running separate analyses for each level separately (e.g., each run, each subject, and then across subjects) before aggregating results and, additionally, it does not require the expensive re-shuffling procedures necessary for *post hoc* inflated false positive control (e.g., for searchlight multi-voxel pattern analysis (Allefeld and Haynes, 2014)).

6. Discussion

In this work, we have proposed a new framework for modeling and analyzing task-based fMRI data using deep generative models. More specifically, we nest a deep convolutional auto-encoder inside a GAM framework so as to produce separate and interpretable covariate effect maps. These effect maps are in turn scaled by covariate-specific gains modeled as the

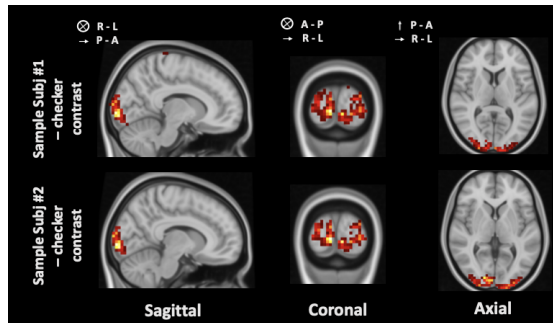

Figure 5: **Single subject task effect maps for 2 sample participants.** Each map was generated by averaging over all task-containing volume reconstructions for a given subject. Note that the exact location and spatial extent of inferred task covariate effects varies slightly from subject to subject. Maps are displayed at the location at which the main activation cluster is most easily visible for a given subject.

sum of a best linear effect estimate and a potential non-linearity (modeled by covariate-specific, one-dimensional Gaussian processes). This approach not only maintains the highly desirable properties of existing fMRI analysis methods (effect separability, generation of spatial effect maps) but also provides more flexibility (e.g., potential non-linear gains) and avoids known drawbacks encountered with the standard GLM approach. For instance, the VAE-GAM framework proposed here models entire volumes at once, which allows it to better account for the inherent spatial auto-correlations observed in fMRI data and avoids some of the statistical testing challenges like inflated false positive rates that require careful correction in the mass-univariate approach.

As we have shown, the proposed VAE-GAM model allows us to correctly recover the shape, size and location of a known synthetic signal added to BOLD data. Additionally, it is capable of producing higher-quality effect maps for true biological signals of interest. In particular, our maps exhibit smoother effect clusters, fewer spurious voxels outside of the main effect cluster, and effect maps for individual participants.

Taken together, the results presented here suggest that deep generative models might provide a new approach to analyzing fMRI data while accounting for some of the modeling challenges inherent to this imaging modality. Ultimately, a more flexible fMRI analysis approach based on a reduced dimensionality latent variable might better model effects of interest to neuroscientists and clinicians, particularly patterns of structured *spatiotemporal* activity associated with cognitive functions and disease processes. Therefore, developing, validating, and perfecting models like this one should be of great value to *both* basic and clinical neuroscience research communities.

Limitations Here, we do not directly attempt to incorporate the temporal autocorrelation inherent in fMRI data into our generative structure. Instead, we model this time dependency indirectly using a convolution operation between the stimulus function and the hemodynamic response curve, in a similar manner to what is typically done in a standard

GLM analysis. Although we do not directly tackle this issue here, modeling a time series of volumes directly and generating a corresponding sequence of latent variables (Naesseth et al., 2018; Le et al., 2017; Maddison et al., 2017) will yield an even more flexible modeling framework, capable of accounting for both spatial and temporal effect variations which is not achieved by any fMRI analysis method currently in use.

Another limitation lies in the fact that VAEs are known to underestimate posterior variance and, therefore, might yield overconfident results (Böhm et al., 2019). Addressing this issue and arriving at a model capable of providing strong statistical guarantees to researchers interested in quantifying and comparing effect sizes across subjects and conditions is also an important area for improvement. Developing such tools would also be broadly interesting and relevant to the ML community, as it would address a major problem encountered in calibrating VAE-based models.

We also note that, in our current model structure, the latent variables produced by the encoder network (\mathbf{z}_t) likely capture some covariate-specific information, along with anatomical (spatial) and temporal information. That is, covariate-specific information is likely not entirely modelled by $\gamma(c_{t\alpha})$. Here, adversarial approaches that attempt to decode task covariates $c_{t\alpha}$ from latent variables \mathbf{z}_t could prove useful in reducing mutual information between these sets of variables and so providing a cleaner distinction between task-specific effects and anatomical and temporal information.
